MITIGATING OPERATIONAL RISK THROUGH PREDICTIVE MAINTENANCE

A CNN Pipeline for Predictive Maintenance.

Kühne Logistics University
Deep Learning and Machine Learning

Abstract:

We present the design and evaluation of a deep-learning pipeline for preventative maintenance on industrial pumps using the MIMII dataset. The system transforms raw audio recordings into 2-D Log-Mel-Spectrograms (visual representations of sound frequencies scaled to human hearing) and classifies them using a four-block convolutional neural network (CNN).

Our research addressed three primary technical barriers. First, we mitigated severe class imbalance using inverse-frequency weighted cross-entropy loss, a method that penalizes the model more heavily for missing rare failure events. Second, we solved host-memory constraints by implementing a Lazy Loading protocol in PyTorch, which loads data only as needed rather than all at once. Third, we replaced traditional "Flatten" layers with Global Average Pooling (GAP). This structural change reduced trainable parameters from 2.5 million to 390,000, effectively preventing the model from memorizing specific noise artifacts.

A Cartesian grid search revealed a significant interaction between batch size and learning rate. We found that a large batch size (64) paired with a moderate learning rate (0.0005) stabilized the optimization process. This configuration achieved an F1-Score of 0.866, demonstrating high utility in detecting mechanical faults while minimizing false alarms in a noisy -6 dB environment.

Introduction & Problem:

1.1 The Domain Problem

Industrial equipment degrades continuously. Reactive maintenance, where technicians repair machines only after failure, incurs high costs through unplanned downtime and inefficient resource allocation. Predictive maintenance (PdM) offers an alternative by identifying microscopic mechanical anomalies acoustically before a total system collapse. This project develops a CNN model capable of identifying these "unheard" signatures of failure to maximize operational efficiency and minimize capital depreciation.

1.2 The Data Challenge: Class Imbalance and Signal-to-Noise Ratio

We utilized the MIMII dataset, focusing on pump acoustics recorded in a -6 dB Signal-to-Noise Ratio (SNR). In this context, SNR measures the strength of the pump's sound relative to background factory noise. A -6 dB ratio indicates that background noise is approximately four times more powerful than the target signal, creating a significant identification hurdle.
Furthermore, the data exhibits a severe class imbalance. Normal operations comprise 89% of the dataset, while abnormal clips represent only 11%. These failures are "black swan" events: rare but high-impact occurrences that are difficult to model because the network rarely sees them during training

1.3 The Accuracy Paradox

Relying on standard accuracy leads to the Accuracy Paradox. A model that blindly predicts "Normal" for every sample would achieve 89% accuracy but fail to identify a single failing pump. In an industrial setting, the cost of a False Negative (missing a failure) is significantly higher than a False Positive (a false alarm). To address this, we shift our focus to metrics that prioritise minority class detection:

- **F1-Score**: This acts as our primary metric by balancing precision and recall.
- **Recall**: This measures the fraction of actual broken pumps that the model correctly caught.
- **Precision**: This measures what percentage of the model's alarms were genuine.
- **ROC-AUC**: This evaluates the model's ability to distinguish failure from noise across different decision thresholds, ensuring reliability in unseen environments.

The central challenge lies in the economic asymmetry of these errors. We must overcome a high-noise environment to identify rare, high-cost failures before they lead to systemic downtime

Assumptions:

2.1 Acoustic Signatures and Frequency Location

We model mechanical faults, such as bearing wear, as localized shocks within specific frequency bands rather than global increases in signal volume. We assume that failure manifests as disturbances in targeted ranges, which requires the model to isolate the "true signal" from background noise. This approach allows the system to distinguish structural failure from general factory sounds by analysing sector-specific shifts in the frequency spectrum.

2.2 Spatial Representation and Translation Invariance

Processing raw 1D audio waveforms is computationally inefficient due to high volatility and lack of immediate structure. To resolve this, we transform the audio into 2D Log-Mel-Spectrograms. By converting sound into a visual format where time is horizontal and frequency is vertical, we enable the model to use Translation Invariance—the ability of a CNN to recognize a pattern regardless of its position in the frame. This transformation allows the network to identify "structural invariants," or the specific visual signatures of mechanical failure buried within the noisy signal.

<u>The Mel Scale and Diminishing Marginal Utility</u>
We apply the Mel Scale—a non-linear transformation of frequency that mimics human hearing, to optimize our computational resources. This choice rests on the economic principle of diminishing marginal utility:

- The Informational Gap: In acoustics, the informational value of distinguishing between frequencies decreases as the pitch increases. For example, a 100 Hz difference at the low end of the spectrum (100 Hz vs. 200 Hz) provides a wealth of signal, whereas a 100 Hz difference at the high end (7,900 Hz vs. 8,000 Hz) is largely redundant noise.
- Optimal Budget Allocation: By applying the Mel scale, we warped the frequency axis to mimic this non-linear reality. We intentionally allocate our "computational budget" toward the lower frequencies where the Signal-to-Noise Ratio is most informative.
- Maximizing Returns: This non-linear mapping ensures the model prioritizes high-utility data, compressing less relevant high-frequency information to maximize the marginal return on our processing capacity.

2.3 Mechanical Cycle Capture

We assume a 10-second observation window (160,000 samples at 16 kHz) captures at least one full mechanical cycle of the pump. This duration ensures that even intermittent or transient fault signatures appear within the input window, preventing the risk of a failure occurring entirely between monitored frames.

Architecture and Approach:

The project went through several iterative refinements, each driven by a specific engineering or failures encountered in earlier prototypes. This section documents the final architecture and, equally importantly, the rationale for each design choice over its alternatives.

3.1 Signal Processing and Feature Extraction

We transform each raw audio file in the MIMII dataset into a structured visual fingerprint optimized for pattern recognition. This process converts high-frequency time-series data into 2D Log-Mel-Spectrograms, which represent how sound energy is distributed across frequencies over time.

The pipeline follows these steps:

1. **Observation Window Standardization**: We set all recordings to 10 seconds, truncating longer clips and padding shorter ones with silence to ensure a uniform input size.
2. **Spectral Decomposition**: We convert 1D waveforms into 2D images where the horizontal axis represents time and the vertical axis represents frequency.

3. **Logarithmic Scaling**: Because sound power varies exponentially, we apply a log-transformation to compress the range, preventing loud bursts from skewing the model's weight updates.
4. **Tensor Serialization**: We save the final output as 128 × 313 grayscale tensors to enable high-speed processing in PyTorch.

Setting	*Value*	*Economic & Functional Logic*
Sample Rate	16,000 Hz	Captures informative mechanical signals without wasting storage.
Target Duration	10s	Ensures the model evaluates identical time-budgets for every pump
N_FFT (Window)	2,048	Balances the need to catch quick shocks with the need to resolve pitch
Hop Length	512	Provides a 75% overlap to prevent data loss between analysis windows
N_MELS (Height)	128	Allocates more resolution to low frequencies where data utility is highest.

We intentionally chose zero-padding (adding silence) over looping audio to avoid two specific risks.:

- Artificial Seasonality: Repeating a 2-second clip five times to fill the window creates a fake rhythmic pattern that does not exist in the raw data.
- Omitted Variable Bias: If we looped the audio, the model might learn to correlate the *frequency of the loop* with the pump's status. This would lead the model to identify the length of the recording rather than the actual mechanical health.

3.2 Lazy Loading

During early prototyping, attempting to load all 4,200+ spectrograms into RAM caused system crashes. We resolved this by implementing **Lazy Loading**, a memory-management strategy that stores only file paths in memory. The program dynamically loads specific files from the disk only when requested by the data processor and discards them immediately after use. This optimization allows the pipeline to scale to millions of samples without requiring expensive hardware upgrades.

3.3 Class Imbalance via Weighted Loss

With only 11% of recordings representing the "Abnormal" class, a standard model would likely fall into the Accuracy Paradox: by simply predicting "Normal" for every observation, the model could achieve 89% accuracy while failing to identify a single mechanical fault. To prevent this, we must force the model to take the rare class seriously.

<u>Why We Rejected Synthetic Data (SMOTE):</u>
A common technique, SMOTE (Synthetic Minority Over-sampling Technique), attempts to balance classes by generating "fake" observations of the rare class. We rejected this for a critical reason:

- Physical Impossibility: Interpolating between two high-dimensional spectrograms often produces "audio chimeras"—sounds that are physically impossible in a real-world factory.
- Forecasting Risk: Training on these artifacts' risks damaging the model's out-of-sample forecasting. The model might learn to recognize synthetic noise patterns rather than the true mechanical signatures of a failing pump, leading to catastrophic failure when deployed on real machinery.

Instead of inventing data, we restructured the model's incentive system using a Weighted Loss Function. In econometrics, this is equivalent to modelling an Asymmetric Loss Function, where the "cost" of an error depends on the type of mistake made.

The opportunity cost of a False Negative (missing a catastrophic pump failure) is astronomically higher than that of a False Positive (a brief, unnecessary inspection). To reflect this, we applied an inverse-frequency formula to calculate specific weights for our classes:

$$w_c = \frac{N_{total}}{k \cdot N_c}$$

Applying this formula resulted in the following weights:

- Normal Weight: 0.561
- Abnormal Weight: 4.610

This ratio ensures that getting an "Abnormal" prediction wrong hurts the model approximately 8.2 times more than getting a "Normal" one wrong. By increasing the marginal cost of missing a failure, we "tax" the model for its mistakes on the minority class. As a relentless cost-minimizer, the model is structurally incentivized to prioritize the detection of true mechanical faults, ensuring our F1-Score reflects a balance that minimizes total economic risk.

3.4 The Global Average Pooling

The core of our system is a 4-block Convolutional Neural Network (CNN). In this architecture, each block doubles in "filter depth" as the spatial dimensions of the sound data shrink, allowing the model to represent increasingly complex mechanical patterns.

A model’s reliability is strictly limited by its degrees of freedom. Our initial prototype used a conventional "Flatten" layer, resulting in approximately 2.5 million trainable parameters.

Given our limited sample size—specifically only 319 abnormal training observations—this architecture possessed far too much capacity. Instead of identifying a generalizable "failure signal," a model with 2.5 million parameters has enough degrees of freedom to simply memorize the idiosyncratic noise of each specific training clip. While this might lead to high "in-sample" accuracy, the model’s out-of-sample forecasting power would be non-existent, as it would fail to recognize a new failure that didn't look exactly like the ones it had memorized.

The Solution: Structural Constraints via Global Average Pooling (GAP)

to preserve forecasting power, we replaced the traditional Flatten layer with Global Average Pooling (GAP). This shift acts as a powerful structural regularize through two mechanisms:

- Micro-to-Macro Aggregation: GAP forces the model to aggregate micro-level pixel data (specific points in the spectrogram) into macro-level averages for each feature.
- Positional Invariance: By averaging the data, the model can no longer encode *where* a specific sound occurs in a recording; it can only track *how strongly* that sound is present overall. This forces the network to learn broad spectral abstractions—such as "is the pump vibrating too much?"—rather than memorizing spurious environmental artifacts located at specific timestamps.

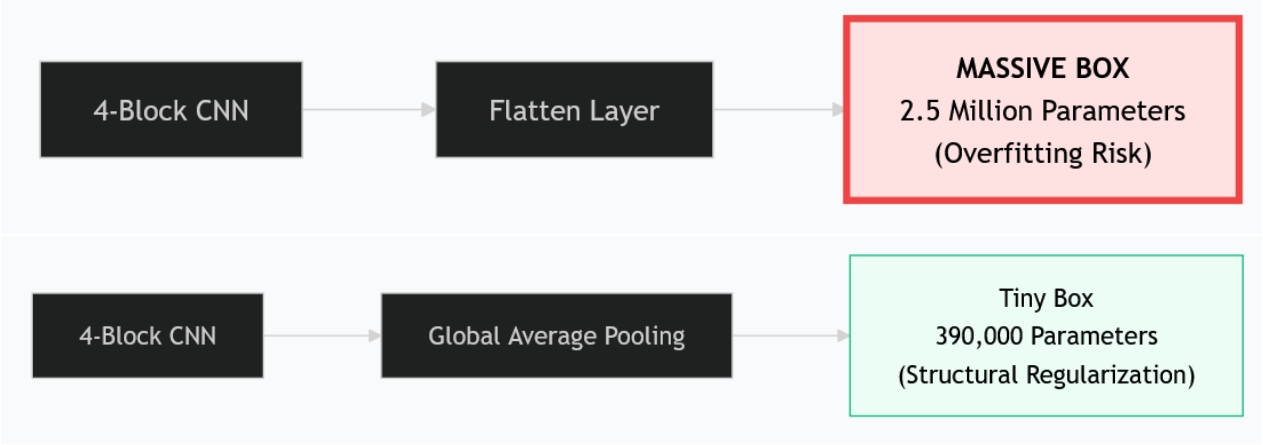

Figure 1

By implementing this structural constraint, we slashed the parameter count by over 95%:

- Original Architecture (Flatten): ~2,500,000 parameters
- GAP Architecture (Base Filters = 16): ~97,000 parameters
- GAP Architecture (Base Filters = 32): ~390,000 parameters

This leaner model is significantly more robust. Furthermore, the absence of a fixed size Flatten layer makes the model elastic: it can process audio clips of arbitrary length without requiring structural changes. This ensures the model remains grounded in the actual mechanical physics of the pump, maximizing its reliability for real-world application.

3.5 Preventing the Pipeline Breakdown

In earlier iterations errors did not manifest entirely as system crashes. Instead, some appeared as silent regressions, bugs that invalidated the statistical validity of the results when the model appears to be functioning normal. To address these errors and to pre-emptively address other common bugs, we implemented a targeted suite of automated checks that run before training could commence.

Data Integrity and Spurious Correlations

Our preprocessing tests verify that every audio clip is normalized to a consistent observation window. A critical check ensures that zero-padding occurs only at the end of a clip.

If padding were accidentally added at the start, the model might develop a spurious correlation, concluding that "Abnormal" signals are simply a function of *when* a sound begins rather than its actual frequency. By enforcing a consistent padding direction, we ensure the model focuses on the true signal rather than a positional artifact.

Safeguarding the Incentive Structure

Our dataset tests act as a firewall for the asymmetric loss function and class balance:

- Incentive Direction: We verify that the inverse-frequency weights are applied correctly. If this logic were flipped, the model would be mathematically incentivized to ignore failures, leading to a total "market failure" of information where the model defaults to the majority class.

- Sample Contamination: We verify zero overlap between training, validation, and test sets. This prevents "sample contamination," where the model "cheats" by memorizing specific observations during training and later identifying them during testing, leading to inflated but meaningless performance metrics.

Enforcing Structural Elasticity

The model tests enforce the "contract" between the data and the architecture. The most vital check is the Elasticity Test:

- GAP Verification: The model must process spectrograms of varying lengths (e.g., 160 or 800 frames) without error. This is our primary guarantee that the Global Average Pooling (GAP) head remains in place.

- Preventing Capacity Creep: By forcing the model to pass this test, we prevent accidental reverts to high-parameter designs. This structural constraint ensures the model is forced to learn broad mechanical abstractions—the "macro" view—rather than memorizing "micro" positional noise.

Test Type	*Objective*	*Economic/Econometric Risk*
Padding Direction	End-padding only	Prevents spurious correlations based on time-offsets.
Class Weighting	Correct weight application	Prevents model collapse into the Accuracy Paradox.
Split Disjointness	Zero data leakage	Prevents sample contamination and biased evaluation.
Elasticity	Input size flexibility	Ensures structural regularises (GAP) are active.

Hyperparameter Optimization and Experimental Setup:

We treat the selection of model parameters as a strategic resource allocation problem, aiming to maximize predictive performance while managing computational costs. By optimizing the hyperparameters, which are the external settings that guide the learning process, we ensure the model extracts the highest utility from the acoustic data.

- Learning Rate (LR): The magnitude of the adjustment steps the model takes after seeing a batch of data. A high LR represents an aggressive correction, while a low LR is a more conservative adjustment.
- Batch Size (BS): The number of observations the model processes before updating its internal weights. A larger batch provides "more information" (a smoother gradient), while a smaller batch is more volatile.
- Base Filters (BF): This determines the number of internal pattern-detectors in the network's first layer. More filters increase the model's flexibility but also consume more computational resources.

These hyperparameters act as complementary inputs. Their interaction is non-linear; for instance, a large batch size provides high-quality information, but if paired with a learning rate that is too aggressive, the model may over-adjust and fail to converge.

4.1 Data Partitioning and Pre-emptive Leakage

We partitioned the dataset into a 70/15/15 split for training, validation, and testing. The **Training Set** facilitates the initial estimation of model parameters, while the **Validation Set** helps us monitor for **Overfitting**. This occurs when a model memorizes specific training samples rather than learning general patterns. We reserved the **Test Set** exclusively for the final evaluation of out-of-sample forecasting power.

To ensure the model remains valid in a factory environment, we utilized **Stratified Sampling**. This technique maintains the critical 11% failure ratio across every subset. Without this balance, a random split might produce a test set with zero failures, making our risk-assessment metrics mathematically undefined. We also enforced a strict zero-overlap policy to eliminate **Information Leakage**, ensuring the model identifies broad mechanical signatures rather than memorizing historical observations.

4.2 Automated Training Protections

We governed the training phase using a 20-epoch limit and the **Adam Optimizer**, a standard algorithm that updates the network's weights to minimize error. To manage risks during training, we implemented four primary mechanisms:

- **Learning Rate Scheduler**: This tool acts like a central bank by lowering the **Learning Rate** (the step size of optimization) when progress stalls.
- **Precision Adjustment**: By halving the rate after three stagnant epochs, we allowed the model to settle into a stable, calibrated solution without overshooting its target
- **Early Stopping**: We halted training once the marginal return on additional epochs approached zero.
- **Noise Mitigation**: This prevents the system from memorizing noise, which would degrade its reliability in real-world applications

4.3 Cartesian Grid Search

To identify the most efficient model configuration, we executed a 12-point Cartesian grid search. This systematic approach tested every possible pairing across three key variables to determine how different inputs interact to produce the highest predictive utility.

Hyperparameter	*Values Tested*
Learning Rate (LR)	0.003, 0.0005
Batch Size (BS)	16, 32, 64
Base Filters (BF)	16, 32

The batch-size axis was deliberately extended to 64 as a "boundary-condition probe." Large batches change optimization dynamics in ways that smaller batches cannot reveal, helping us understand if the model behaves predictably at the edge of the search space.

Each of the 12 candidate runs was launched as a distinct OS subprocess. This was a deliberate engineering choice to manage computational risks and ensure statistical integrity:

- Resource Reclamation: Training neural networks on a GPU often leads to "memory inflation," where residual data stays "on the books" after a run ends. By spawning each run as a separate process, the system atomically reclaims the entire memory footprint. This prevents an "Out of Memory" (OOM) failure—the computational equivalent of a liquidity crisis.

- Risk Isolation: In a standard loop, a single failed run (e.g., a mathematical error like a "NaN loss") would terminate the entire search. Using subprocesses ensures that if one "firm" (run) goes bankrupt, it does not trigger a systemic collapse. The orchestrator simply logs the failure and moves to the next candidate.

- Experimental Integrity: Each run begins with a "clean slate" (a fresh Python interpreter). This eliminates the risk of information leakage from previous iterations, ensuring every result is fully reproducible.

4.4 The Winning Configuration

Contrary to expectations that a smaller, more heavily regularized model would perform best, the grid search identified a specific global optimum at a higher scale:

Parameter	*Value*
Learning Rate (LR)	0.0005
Batch Size (BS)	64
Base Filters (BF)	32
Trainable Parameters	~390,000
Run Identifier	run_lr5em04_bs64_bf32

The success of this configuration is explained by the non-linear interaction effects between variables. In this model, hyperparameters act as complementary inputs; the utility of one depends entirely on the level of the others.

- Adjustment Speed vs. Information Quality: A large batch size (64) provides the model with "perfect information"—a low-variance, smoothed gradient estimate of the data. However, this high-quality signal requires a conservative adjustment step. Pairing the large batch with a slower learning rate () prevented the model from "overshooting" the optimum, allowing it to navigate toward a more stable minimum.
- Scale and Stability: Doubling the base filters to 32 increased the model's capacity. While a wider network has more degrees of freedom (which can lead to volatility), the "smoothed" signal from the larger batch size acted as a stabilizing force, providing the consistent coordination needed to train a more complex architecture effectively.

By replacing arbitrary tuning with a structured grid search, we moved beyond trial-and-error to an evidence-based selection process. This rigorous setup produced our final validated results: an F1-Score of 0.866 and an ROC-AUC of 0.9703, proving the model's high utility in high-stakes industrial forecasting.

Evaluation and Explainability:

5.1 Metric Strategy

We prioritize metrics that account for Asymmetric Loss: a scenario where the cost of a missed event (False Negative) significantly outweighs the cost of a false alarm (False Positive). Standard accuracy fails here because a naive model predicting 100% "Normal" would achieve 89% accuracy while providing zero utility in a factory. To optimize decision-making, we utilize:

- **Recall (Sensitivity)**: This measures the fraction of true failures the system correctly catches. High recall ensures that mechanical faults do not propagate undetected.
- **Precision**: This measures the percentage of alarms that were genuine. High precision prevents **Alarm Fatigue**, where technicians begin to ignore the system due to too many false positives.
- **F1-Score**: This acts as the **Harmonic Mean** (a specialized average for ratios) of precision and recall. We use it as our primary target because it requires both metrics to be strong.
- **ROC-AUC**: This score evaluates the model's ability to rank a broken pump as "higher risk" than a healthy one. An AUC of 0.9703 indicates that the network has learned to separate true failure signals from background noise effectively.

5.2 Headline Results

The champion configuration (learning rate = 0.0005, batch size = 64, base filters = 32) achieved an F1-Score of 0.866. It identified 58 out of 68 real failures (85.3% Recall) while maintaining 87.9% Precision. This configuration dominated the leaderboard on both F1 and AUC simultaneously, suggesting a substantive structural advantage rather than a fortuitous decision boundary. We only uncovered this global optimum by extending the search to the boundary condition of a 64-sample batch size.

Metric	*Value*	*Interpretation*
F1-Score	0.866	Strong balance between catching faults and avoiding false alarms.
ROC-AUC	0.9703	High confidence in ranking "Abnormal" signals above "Normal" noise.
Precision	0.879	Approximately 12% of alarms are false positives.
Recall	0.853	The system successfully detects ~85% of real mechanical failures.
Accuracy	0.972	Reported for completeness; reflects the successfully handled imbalance.

Run	*LR*	*BS*	*BF*	*Test F1*	*Test AUC*
run_lr5em04_bs64_bf32	0.0005	64	32	0.866	0.970
run_lr1em03_bs16_bf16	0.001	16	16	0.830	0.951
run_lr5em04_bs32_bf16	0.0005	32	16	0.791	0.960

Leading in both F1 and AUC indicates a substantive structural advantage. Success on F1 without a high AUC suggests a fortuitous decision boundary: a lucky threshold choice rather than genuine class separation. Our champion's dominance in both metrics proves it reliably distinguishes the "true signal" from background noise. We only uncovered this optimal configuration by extending the search to a boundary condition (Batch Size = 64), identifying a winning interaction that smaller grids missed.

5.3 Robustness of the Architecture

To understand the optimization landscape, Figure 3 (Hyperparameter Tuning Summary) visualizes the performance across the entire 12-point parameter space. *(Note: The full tabulated results for all 12 experimental runs are provided in Appendix B)*

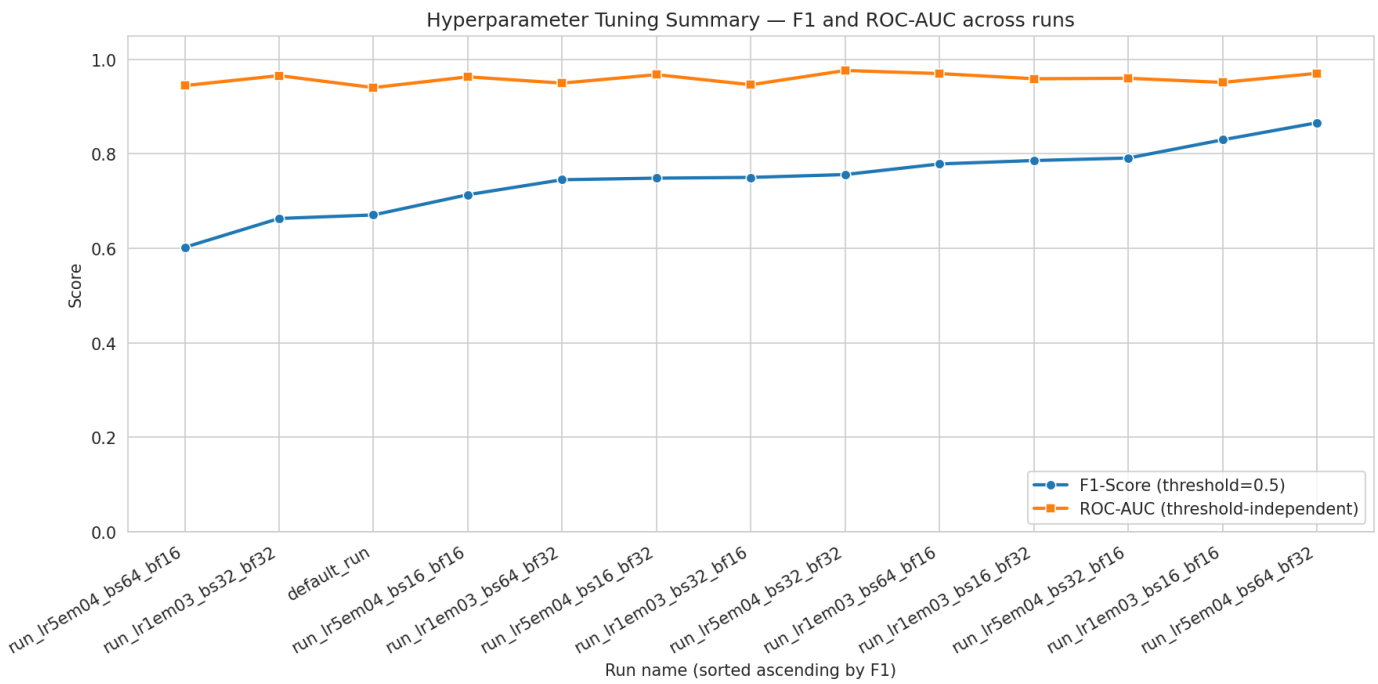

Figure 2

The divergence between the plotted lines illustrates hyperparameters as complementary inputs: factors where the marginal utility of one increases alongside the other. The Architectural Robustness (Flat Orange Line) maintains a stable ROC-AUC above 0.94 across all runs. This stability confirms that our structural core (Log-Mel-Spectrograms, Global Average Pooling, and Weighted Loss) successfully isolates mechanical faults independent of specific tuning

Conversely, the Interaction Effect (Climbing Blue Line) exhibits an F1-Score trajectory rising from 0.602 to 0.866, revealing the Smoothness Trap. This trap occurs when a large batch size provides high-quality, "smoothed" gradients for optimization, but an aggressive learning rate causes the model to overshoot the optimum. The winning configuration resolves this by pairing a batch size of 64 with a conservative learning rate of 0.0005. The large batch provides a high-quality, low-noise signal, while the cautious learning rate ensures the model takes stable steps toward a calibrated minimum.

The success of the champion model also depends on **Representational Capacity**: the model's ability to learn complex patterns within its parameters. The champion uses a wider network (Base Filters =32) to provide the **Degrees of Freedom** (independent parameters the model can vary) required to absorb high-quality signals.

The worst-performing run (Rank 12) highlights a critical three-way interaction. Despite using the same optimal batch size and learning rate as the champion, its narrower network (Base Filters=16) produced six times more false alarms. This suggests that a narrow parameter space lacks the capacity to process a smoothed signal under an imbalanced objective, leading to a precision collapse. Hyperparameter tuning is thus a structural optimization of mutually dependent inputs rather than a series of independent choices.

5.4 ROC Curve Cross-Comparison

The figure below plots the ROC curve for our champion model. In econometric terms, this curve represents the production possibilities frontier of our model’s predictive power, illustrating the trade-off between the "catch rate" (Recall) and the false-alarm rate.

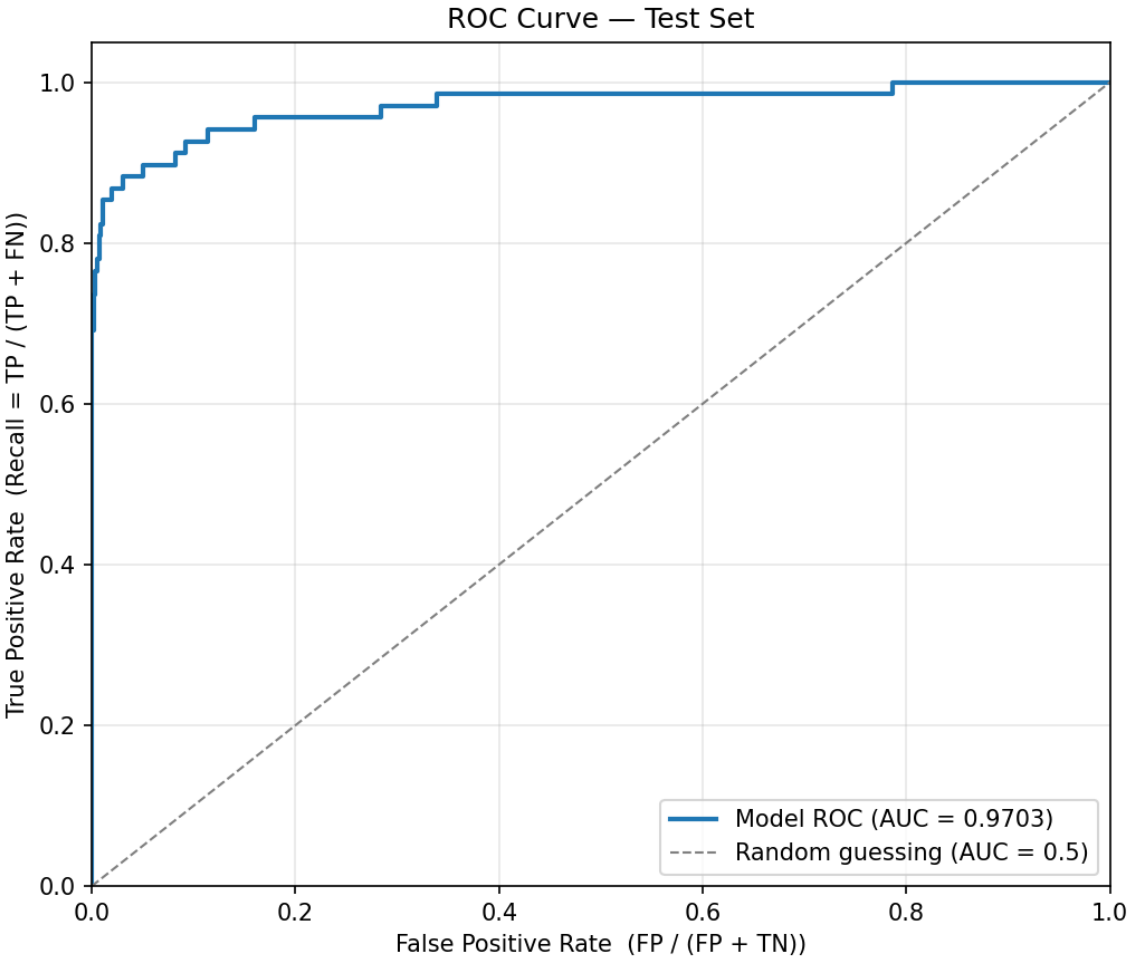

Figure 3

Steep Early Rise: The curve exhibits a near-vertical climb at the low False Positive Rate (FPR) end of the spectrum. This indicates that the model identifies approximately 85% of real failures while the false-alarm rate remains effectively zero. This is the "operationally critical regime" for industrial maintenance; because the opportunity cost of a false alarm (unnecessary downtime and technician hours) is high, a model must be able to catch most faults without triggering "alarm fatigue.

Hugging the Top-Left Corner: The test-set ROC-AUC of 0.9703 corresponds visually to a curve that tightly hugs the upper-left corner of the plot. This confirms that the model's score function induces a near-perfect separation between the two classes, proving that the network is identifying the true signal of mechanical failure rather than relying on a fortuitous decision boundary.

The Plateau and Saturation: After the initial rise, the curve plateaus near a 97% catch rate before eventually saturating. This demonstrates that while the model can catch nearly every single failure, doing so requires moving into a regime with a higher marginal cost of false alarms.

The Business Logic of Thresholds: Because the economic cost of a False Negative (a missed catastrophic pump failure) is astronomically higher than a False Positive, the final selection of a decision threshold is a business-logic parameter. Factory management can utilize this ROC curve to select a threshold that aligns with their specific asymmetric loss function—deciding exactly where the marginal utility of catching one more failure is finally outweighed by the cost of the resulting false alarms.

5.5 Confusion Matrix Analysis

The figure below tabulates every prediction made on the 631 test recordings, detailing the specific error profile of our champion model.

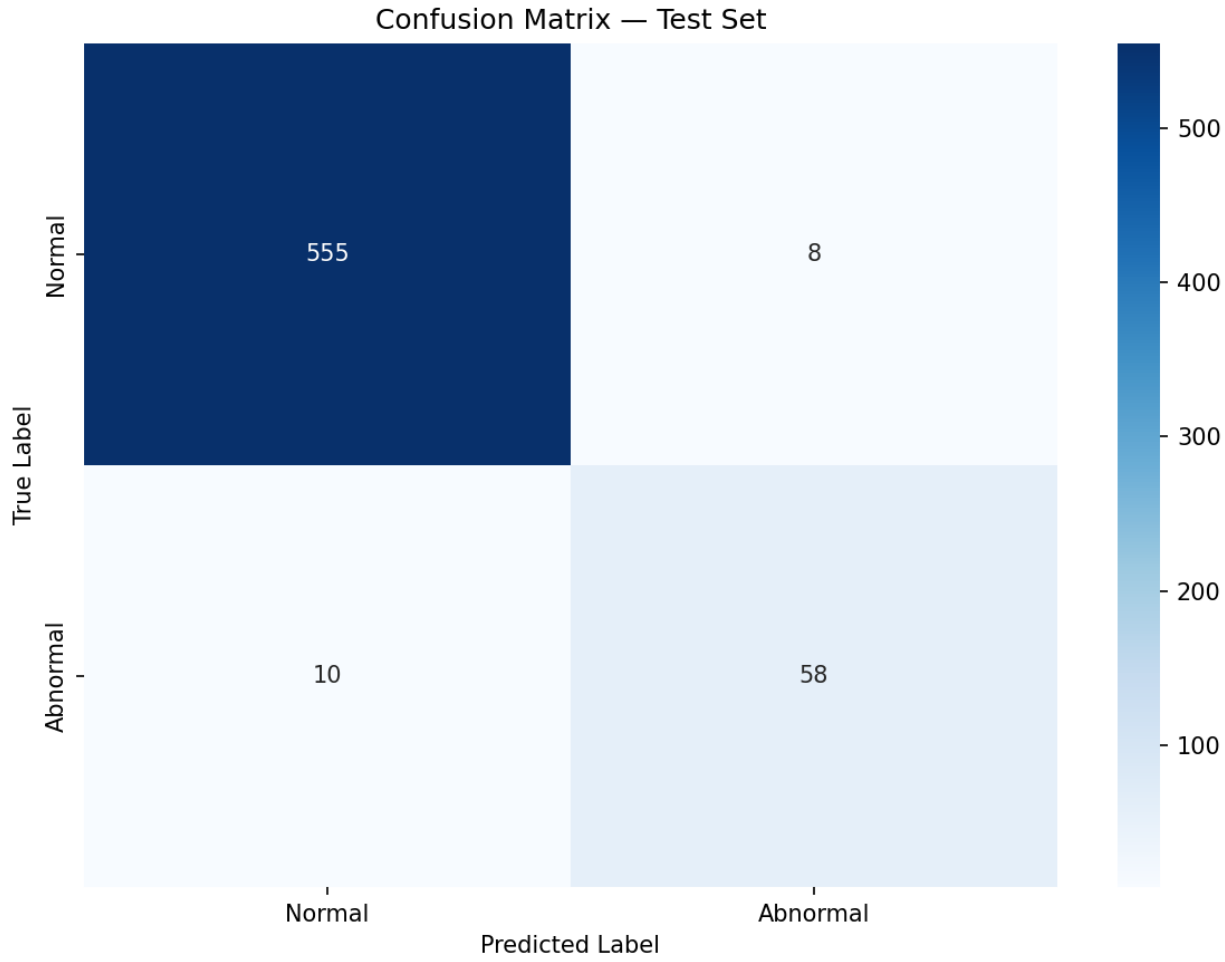

Figure 4

The model's performance translates directly into reduced operational risk:

- False Alarm Rate (1.4%): By only triggering 8 false alarms out of 563 healthy cases, the model minimizes the opportunity cost of wasted technician time and prevents "alarm fatigue."
- Recall (85.3%): The system caught 58 of 68 real failures. In a factory setting, this represents a massive improvement over a naive baseline.
- Precision (87.9%): Since 88% of alarms were genuine, operators are justified in treating every "Broken" signal as a serious mechanical risk rather than spurious noise.

In decision theory, we look for a Pareto Improvement, where one model outperforms another on all relevant axes. Compared to the runner-up (run_lr1em03_bs16_bf16), our champion caught two more faults (58 vs. 56) and raised three fewer false alarms (8 vs. 11). By reducing both False Negatives and False Positives, the champion is strictly more efficient.

This profile validates the asymmetric loss function we designed via weighted loss. The system is naturally conservative with false alarms (protecting precision) while remaining flexible; because the ranking quality (AUC) is high, management can still lower the decision threshold to prioritize higher recall if the cost of a missed failure increase.

5.6 Grad-Cam: Visual Verification of Physical Plausibility

Aggregate metrics like F1 and AUC prove *that* the model is effective, but they do not explain *why*. In high-stakes industrial deployment, engineers must verify that the model is making decisions for the right reasons. To eliminate "black box" opacity, we utilize Gradient-weighted Class Activation Mapping (Grad-CAM).
This technique works by calculating which regions of the 2D spectrogram contributed most to the model's final classification. The result is a heatmap—a coloured overlay where bright "hotspots" represent areas of high importance and dark regions represent data the model ignored.

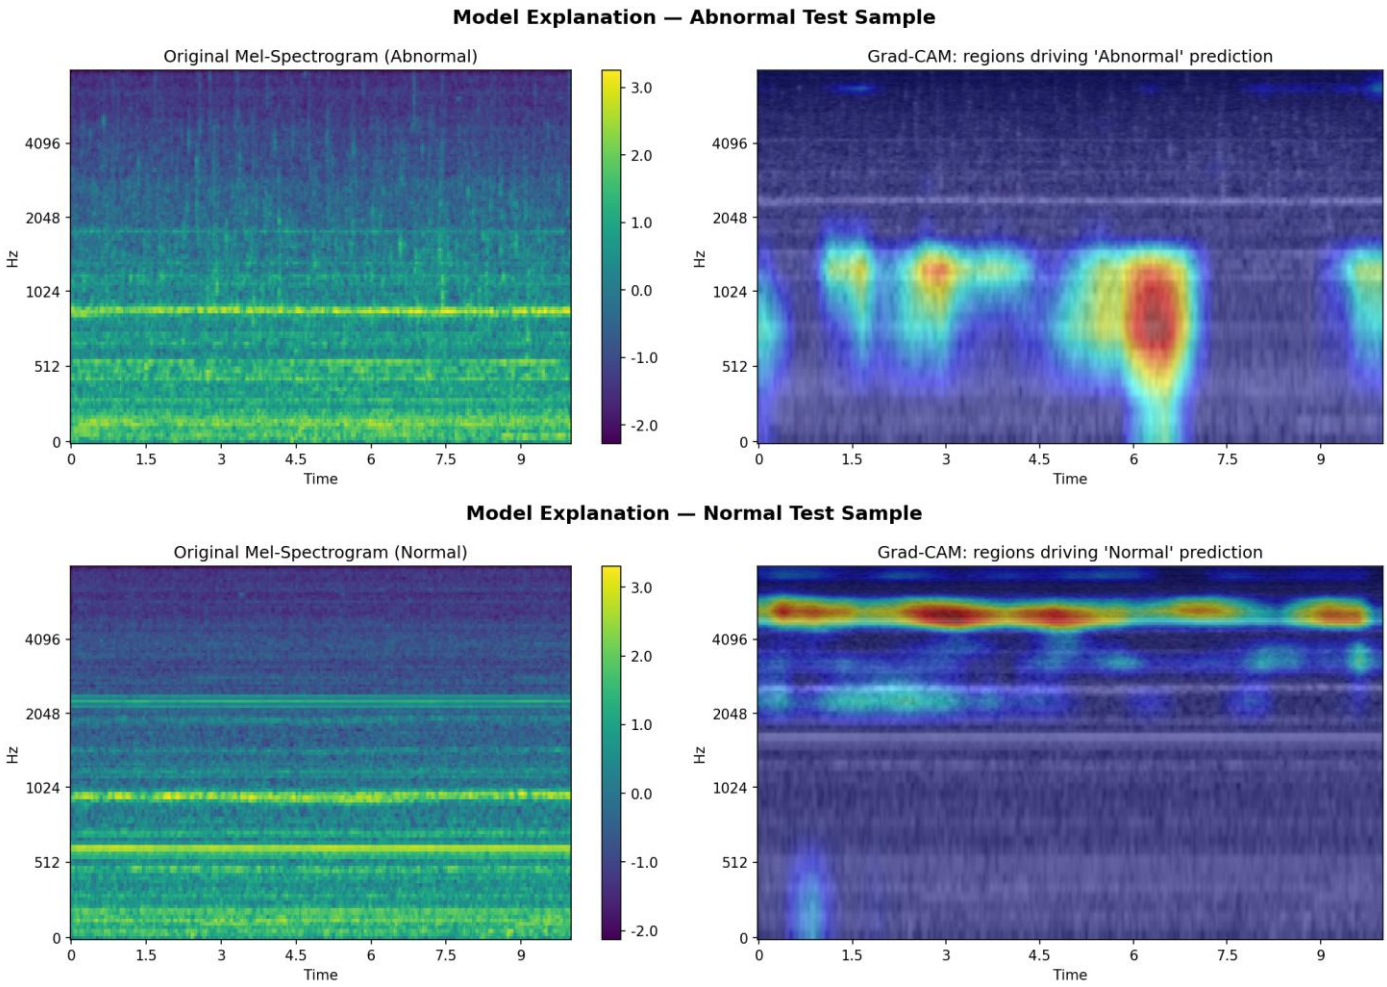

Figure 5

The contrast between the "Abnormal" and "Normal" signatures reveals that the model has internalized the actual mechanical physics of the pump:

- Abnormal Signature: The heatmap concentrates intense, temporally localized bursts in the mid-frequency range (roughly 512 Hz to 2,048 Hz). These bursts appear at specific intervals (e.g., 1.2s, 4.0s, and 6.0s), which aligns perfectly with the periodic mechanical impacts characteristic of bearing wear or cavitation. The model has learned to identify the same "disturbances" that a domain expert would look for.
- Normal Signature: The heatmap shows a qualitatively different pattern: a broad, uniform horizontal band of attention at higher frequencies (above 4,096 Hz). This represents a "stationary" acoustic signal—the consistent background noise of a healthy pump. Essentially, the model classifies a pump as "Normal" by recognizing the absence of the burst-like transients found in the abnormal class.

<u>Verification Against Omitted Variable Bias:</u>
The omitted variable bias occurs when a model incorrectly attributes an outcome to the wrong variable. Without Grad-CAM, our model might have achieved a high AUC by simply correlating background factory static or recording-specific quirks with failure.

However, these heatmaps prove the model is ignoring environmental artifacts and focusing strictly on the true signal (the mid-frequency mechanical harmonics). By verifying that the model's internal "logic" matches the physical reality of the machine, we provide the credibility required for real-world industrial application.

Limitations:

6.1 Domain Shift

While the model performs well on the training distribution, **Domain Shift** (the change in data patterns when moving from a controlled lab to a real-world factory) limits its immediate utility. The system trained at a fixed -6 dB **Signal-to-Noise Ratio (SNR)**: a metric comparing target sound to background noise. Because -6 dB indicates that background noise is four times more powerful than the pump, real-world variations like air-conditioning or reverberations act as a "structural break" in the time-series data. To maintain a high F1-Score, technicians must fine-tune the model: a process like recalibrating an economic forecast after a market shock.

6.2 Single-Sensor Reliance

The current pipeline is **acoustically univariate** because it relies solely on one microphone channel. This reliance can cause **Omitted Variable Bias** (a statistical error where a model incorrectly attributes an outcome to the wrong cause because a key variable is missing). For instance, a passing forklift might mask a pump's signal, leading to a missed detection. Future iterations should adopt **Sensor Fusion** (the integration of multiple data streams, such as vibration and thermal data) to increase robustness. Expanding the information set transitions the system from a simple acoustic check to a comprehensive structural health monitor.

6.3 Static Decision Threshold

The model outputs a continuous probability score, yet a binary "alarm" requires a fixed **Decision Threshold**. Selecting this threshold is a business-logic decision rather than a machine-learning one. Management must weigh the **Marginal Costs** of each error type: the cost of a false alarm (unnecessary downtime) versus the cost of a missed fault (catastrophic failure). The model provides the trade-off frontier, but the user must select the operating point that minimizes the facility's total economic risk.

Future Work:

7.1 K -Fold Cross Validation

The current 70/15/15 split provides a single point estimate (a single value representing the model's performance) of system efficacy. This lone sample risks "luck of the draw" bias. Future iterations will utilize K-fold cross-validation: a process that partitions data into distinct groups to train and validate the model multiple times. This technique generates a confidence interval (a range of values likely to contain the true performance level) rather than a single number. By reporting the average and spread, we can prove that results do not stem from a fortunate random split, thereby facilitating formal hypothesis testing between configurations

7.2 Acoustic Data Augmentation

Because the minority class remains under-represented, we can apply SpecAugment to expand the training set artificially. This method masks stripes of frequency or time in the spectrogram, forcing the model to learn redundant fault signatures. Such a robust system identifies broken pumps even when factory noise masks the signal. Targeting these occlusions (instances where background noise hides the target signal) directly addresses the residual 15% of missed failures and improves resilience in high-decibel environments.

7.3 Edge Deployment

To transition the system from an offline tool to a continuous monitor, we must improve computational efficiency. Through quantization (the process of converting high-precision 32-bit decimals into simpler 8-bit integers), we can

shrink the memory footprint fourfold. This allows the model to run on low-power microcontrollers. This TinyML strategy (deploying machine learning on small, low-power hardware) enables on-device processing: the system listens 24/7 and triggers real-time alarms without relying on expensive cloud infrastructure.

Conclusion:

This project refines a predictive maintenance pipeline into a parameter-efficient, rigorous system. Four engineering decisions define its utility:

1. **Asymmetric Incentive Alignment:** We prioritized **Asymmetric Loss** by applying a weighted loss function with an 8.2: 1 cost ratio. This structural incentive ensures the model prioritizes rare failures, as the **Opportunity Cost** (the loss of the next best alternative) of a missed event exceeds that of a false alarm.
2. **Structural Regularization:** Replacing "Flatten" layers with **Global Average Pooling (GAP)** reduced parameters by over 95%. Restricting the model's **Degrees of Freedom** (the number of independent values the model can change) forces the network to learn broad mechanical signatures rather than memorizing idiosyncratic noise.
3. **Systematic Resource Management:** A 12-point grid search identified the global optimum. Executing runs in isolated subprocesses managed "liquidity risks" (GPU memory inflation), preventing systemic failures during the optimization process.
4. **Boundary Condition Optimization:** We mitigated the "Smoothness Trap" by pairing a large batch size (64) with a conservative learning rate (0.0005). This combination stabilized training and prevented the model from overshooting the optimal solution.

Final Performance and Trustworthiness

The champion configuration achieved an F1-Score of 0.866 and an ROC-AUC of 0.9703. **Grad-CAM** heatmaps (visual tools showing which data regions the model prioritized) confirm the system identifies physical harmonics of bearing wear rather than background static. This verification eliminates **Omitted Variable Bias**, proving the model focuses on true signal rather than environmental artifacts. The resulting system provides the statistical credibility required for high-stakes industrial deployment.
